(Received 11 August 2018; published 24 October 2018)

We study Brownian dynamics of colloidal spheres, with planar anchoring conditions, suspended in the nematic phase of the lyotropic chromonic liquid crystal disodium chromoglycate (DSCG). Unlike typical liquid crystals, the unusually small twist elastic modulus of DSCG permits two energetically distinct helical distortions (twisted tails) of the nematic director to “dress” the suspended spheres. Video microscopy is used to characterize the helical distortions versus particle size and to measure particle mean-square displacements. Diffusion coefficients parallel and perpendicular to the far-field director, and their anisotropy ratio, are different for the two twisted tail configurations. Moreover, the crossover from subdiffusive to diffusive behavior is anomalously slow for motion perpendicular to the director (>100 s). Simple arguments using Miesowicz viscosities and ideas about twist relaxation are suggested to understand the mean-square displacement observations.

The investigation of Brownian dynamics boasts a spectacular history that has produced deep insights about statistical mechanics and about the microscopic environments of diffusing particles [1–4]. Although most of this work concerns the motion of spheres in isotropic media, the effects of anisotropy in Brownian dynamics are proving to be fascinating as well, including the diffusion of anisotropic particles in isotropic fluids [5–10] and particles of all types in anisotropic fluids [11–17].

In this Letter, we explore diffusion of spherical particles in the lyotropic chromonic liquid crystal (LCLC) disodium cromoglycate (DSCG). This background fluid is a nematic liquid crystal (LC) composed of self-assembled achiral rodlike molecular assemblies aligned uniaxially along a director \( \mathbf{n} \) [Fig. 1(a)] [18,19]. As in all LC systems, particles in DSCG are expected to exhibit different coefficients for diffusion parallel versus perpendicular to the director field [11,13,14,16,20]. Lyotropic chromonic liquid crystals are different from typical LCs, however, because they easily form twisted or chiral configurations due to their unusually small twist elastic modulus [21–23], an effect also seen in polymer nematic LC systems [24,25]. Thus the local environment for a sphere diffusing in DSCG has a chiral character that depends sensitively on the interplay of bulk elasticity, local geometry, and director boundary conditions. Indeed, it has been shown [26] that spherical colloidal particles with planar anchoring in the nematic phase of DSCG induce localized helical distortions, i.e., “twisted tails” that extend away from the particle parallel to the uniform far-field director \( \mathbf{n}_0 \) [Figs. 1(b)–1(h)]. The energetics and symmetries of these twisted tail configurations have been studied [26,27], but to our knowledge the effects of chiral distortion of the director on unconstrained particle diffusion have not been considered nor investigated. Moreover, the influence of giant twist elastic anisotropy on relaxation dynamics, broadly defined, has never been explored.

To this end, we employ video and polarized optical microscopy (POM) to investigate diffusion of spheres “dressed” by two classes of chiral director configurations with twisted tails. Diffusion coefficients, parallel and perpendicular to the far-field director, as well as diffusion anisotropy, are revealed to be different for the two classes. In addition, the short-time diffusion dynamics show subdiffusive scaling for motion parallel and perpendicular to the far-field director, and they exhibit anomalously long relaxation times (>100 s) for diffusion perpendicular to \( \mathbf{n}_0 \). We offer qualitative arguments to understand the measured diffusion coefficient anisotropy based on the Miesowicz viscosities of LCLCs, and we show how giant twist elastic anisotropy can introduce differences in the diffusion behavior of the dressed particles. Our results complement and differ from diffusion measurements, reported in Ref. [16], of heavy silica spheres very close to the substrate without director configuration class identified [see Supplemental Material (SM), Sec. IV [28]]. By positioning particles farther from the substrates, our experiments ameliorate surface drag effects and probe the bulk LC response more effectively. These improvements enable us to uncover substantial variation in subdiffusivity parallel versus perpendicular to \( \mathbf{n}_0 \), and to distinguish diffusion of particles dressed by different director field configurations. Broadly, the present work elucidates how chiral structures that readily form in LCLCs can affect the dynamics of
The suspensions consist of diameters $d$ of styrene divinylbenzene (DVB) spheres in DSCG, with typical polydispersity in the source samples is $\sim 1$. Substrate. Since the particle density ($0.05 \, g \, cm^{-3}$) is slightly lower than the density of the DSCG solution ($1.0784 \pm 0.0032 \, g/cm^3$), the particles are weakly driven toward the upper substrate by gravity. We permit the suspensions to equilibrate for 1.5 days before imaging to ensure that particle proximity to the cell substrate is consistent and does not influence measured diffusion (SM, Sec. IV [28]).

Samples are imaged in bright field and POM using a Leica DM IRB inverted microscope with 100x oil objective (N.A. = 1.4). Typically, digital imaging at 60 frames per second over a period of $\sim 15$ min is carried out using a CMOS camera (Mikrotron EoSens CL MC1362). Particle tracking uses standard routines written in IDL computer code [34]. The mean-square displacement (MSD) experimental results are typically generated from $\sim 30$ video trajectories ($\sim 10$ trajectories for 3 particles in each class at each temperature). The MSD curves shown represent an average of these trajectories; error bars reported for diffusion coefficients are derived from fits to the average curves.

The resultant particles in the nematic LCLCs are dressed by twisted tails. In contrast to conventional LC systems, wherein spherical particles with planar anchoring generate topological quadrupoles with large splay and bend distortions in the surrounding nematic [15], the splay and bend elastic energies in LCLCs are reduced by twisting the director. As a result, the character of the elastic distortion in the particle vicinity is novel and varied [Figs. 1(b)–1(g)]. One configuration symmetry (class 1), with the director spiraling around the central axis in the same sense on opposite sides of the colloidal particle, is called a chiral dipole and is characterized as an elastic multipole composed of both quadrupole and chiral dipole terms [27,35,36]. The other director configuration (class 2) is globally nonchiral, because the directorspirals in an opposite sense on opposite sides of the particle and thereby creates a mirror plane of symmetry [red dashed line in Fig. 1(e)]. Generation of either symmetry class is spontaneous and reversible via melting and requenching of the nematic background phase (SM Fig. 3 [28]). The class 1 configuration is calculated to have the lower energy [26]. In our experiments, we observe both configurations with probabilities $\sim 64\%$ for class 1 and $\sim 36\%$ for class 2 (for more details, see SM, Sec. II [28]), which supports the calculations. We do not observe spontaneous transformation of one class to another without reheating the sample.

Director distortions near the particle are predicted to diminish as the sphere radius is decreased [26]. We measured this effect for the first time and report it in Fig. 1(h) for both classes. An estimate for tail length in each

FIG. 1. (a) Illustration of the nematic phase of DSCG. The nematic mesogens are stacks of planklike molecules. (b)–(g) A spherical particle with planar boundary conditions suspended in the uniaxially aligned nematic phase of DSCG induces two distinct twisted tail director configurations: class 1 (b)–(d) and class 2 (e)–(g). Panels (b) and (e) are schematics of twisted director fields (black lines) around the particle. Panels (c) and (f) are cross-polarized (white arrows) microscopy images. Panels (d) and (g) are cross-polarized microscopy images with an inserted full wave plate (green arrow). (h) Tail length plotted as a function of particle radius for both symmetry classes. Dotted lines show best proportional fits for each class (see text).
Motion parallel to results. Figure 2(a) exhibits the salient features of all the surrounding nematic field. Anisotropic and twisted composite objects when dressed by MSD curves parallel and perpendicular to particles employed in the diffusion measurements; the tail data for large diameter particles ( scales with particle radius\cite{26} if the particle is far from the smallest particles ( ) particles are different from ellipsoids. The class 1 and class 2 diffusion anisotropy ratios in Table I, e.g., are significantly larger than for ellipsoids diffusing in 3D, and comparable only to ellipsoids diffusing in quasi-2D \cite{7,37,38}; axis ratios for the dressed spheres based on their measured tail lengths and diameters are \(\sim 3.4\) and \(\sim 2.8\), respectively.

Diffusion anisotropy, resulting from the direction-dependent viscous drag, is typical in nematics, but the Stokes drag on a sphere in a nematic LC is very challenging to calculate \cite{15,20,39,40}. It is governed by Ericksen-Leslie equations that connect fluid flow to the director reorientation via elastic and viscous stresses \cite{13,14,41,42}. The coefficients of the viscous stress tensor, the Leslie coefficients, combine to give three Miesowicz viscosities, \(\eta_a\), \(\eta_b\), and \(\eta_c\), for the three shear geometries shown in Fig. 3(a) (\(\alpha\)-type geometry), Fig. 3(b) (\(\beta\)-type), and

\begin{tabular}{|c|c|c|c|}
\hline
 & Diameter (\(\mu m\)) & \(D_1 \times 10^{-16}\) (m\(^2\)/s) & \(D_\perp \times 10^{-16}\) (m\(^2\)/s) & \(D_1/D_\perp\) \\
\hline
Class 1 & 6.70 ± 0.16 & 2.67 ± 0.18 & 0.515 ± 0.070 & 5.19 \\
Class 2 & 6.59 ± 0.14 & 3.90 ± 0.25 & 1.12 ± 0.11 & 3.48 \\
\hline
\end{tabular}
\end{table}

at long lag times increases with temperature as expected and (2) subdiffusivity persists at all temperatures studied (SM, Sec. V \cite{28}).

The diffusion coefficient anisotropy ratios for the two classes are also shown. Although the dressed spheres do not rotate like ellipsoids, comparison to the diffusion of ellipsoids in isotropic fluids is revealing. Diffusion is slower for motion perpendicular to the ellipsoid long axis, as is the case for the dressed particles. Moreover, the diffusion anisotropy is larger for ellipsoids with larger major/minor axis ratios, just as class 1 particles with larger effective aspect ratios have larger diffusion anisotropies than class 2 particles. However, as expected, the dressed particles are different from ellipsoids. The class 1 and class 2 diffusion anisotropy ratios in Table I, e.g., are significantly larger than for ellipsoids diffusing in 3D, and comparable only to ellipsoids with axis ratios >8 and \(\sim 5\), respectively, diffusing in quasi-2D \cite{7,37,38}; axis ratios for the dressed spheres based on their measured tail lengths and diameters are \(\sim 3.4\) and \(\sim 2.8\), respectively.
Typically, for rodlike nematics [14,20,25], $\eta_b < \eta_a < \eta_c$; thus, we expect $D_\perp > D_\parallel$, as observed. These qualitative estimates are useful because they resemble predictions of simple analytical models using the Ericksen-Leslie equations [20]. However, numerical models addressing planar anchoring at the particle surface show that the dynamic viscosities are generally not simple combinations of the Miesowicz viscosities [20]. Furthermore, the relationships between the Miesowicz viscosities and the dynamic viscosities are further complicated by the helicity and large anisotropy of the chiral director distortions (SM Figs. 7 and 8 [28]). Nevertheless, based on the field symmetry and the size of the overall distortions around the spheres, we expect and observe that class 2 particles [SM Figs. 7(a), 7(c), 8(d), and 8(f) [28]] experience an effective viscosity comparatively more similar to that of a pure (planar) quadrupole than the class 1 particles.

Fig. 3(c) (c-type), respectively. When considering particle diffusion through a uniaxially aligned nematic director configuration, different Miesowicz viscosities make important contributions to the dynamic viscosities, $\eta_{\parallel,\perp}$. For the case of pure (planar) quadrupoles [Figs. 3(d) and 3(e) and SM Figs. 7(a), 8(a), and 8(d) [28]], when the particle moves parallel to $n_0$, the nematic fluid in the shaded regions of Fig. 3(d) [and SM Fig. 7(a)] experiences mostly $b$-type shear, since the larger component of the director is parallel to the fluid velocity and perpendicular to the velocity gradient. The smaller director component is perpendicular to the fluid velocity and parallel to the velocity gradient. For the case of pure (planar) quadrupoles, we expect $\eta_1 < \eta_b < \eta_c$; thus, we expect $D_\parallel > D_\perp$, as observed. These qualitative estimates are useful because they resemble predictions of simple analytical models using the Ericksen-Leslie equations [20]. However, numerical models addressing planar anchoring at the particle surface show that the dynamic viscosities are generally not simple combinations of the Miesowicz viscosities [20]. Furthermore, the relationships between the Miesowicz viscosities and the dynamic viscosities are further complicated by the helicity and large anisotropy of the chiral director distortions (SM Figs. 7 and 8 [28]). Nevertheless, based on the field symmetry and the size of the overall distortions around the spheres, we expect and observe that class 2 particles [SM Figs. 7(a), 7(c), 8(d), and 8(f) [28]] experience an effective viscosity comparatively more similar to that of a pure (planar) quadrupole than the class 1 particles.

Fig. 3(a)–(c) Three shear geometries of a nematic LC between parallel plates corresponding to the three Miesowicz viscosities (a) $\eta_a$, (b) $\eta_b$, and (c) $\eta_c$. (d),(e) Cross-sectional schematic of a spherical particle with tangential surface anchoring suspended in a uniaxially aligned nematic. Black lines represent the equilibrium director field for a stationary particle. Red dashed lines represent perturbations in the director field due to colloidal displacements (depicted by red arrows) either (d) parallel or (e) perpendicular to $n_0$. The green shaded regions are regions of interest when considering the effects of the Miesowicz viscosities (see text and SM [28]). The round arrows to the right indicate that the equilibrium field is axially symmetric. (f) Splay, (g) twist, and (h) bend distortions as predicted by the theoretical ansatz from Ref. [27]. (i)–(n) Calculated changes in the director fields shown in (f)–(h), due to small particle translations ($\Delta x_p$, $\Delta y_p \approx 4.5 \text{ nm}$) both (i)–(k) perpendicular and (l)–(n) parallel to $n_0$. The reference frame and color scale insets in (m) and (n), respectively, apply to (f)–(n).
subdiffusion to normal diffusion will occur on timescales comparable to $t_i$. To derive these timescales, we use measured estimates for the mode viscosities and elastic constants of DSCG at 23 °C [21], and we choose, for simplicity, $l_i = 2 \mu m$ for all cases. These assumptions provide an estimate $t_i$ for each distortion mode: $(t_{\text{splay}}, t_{\text{twist}}, t_{\text{bend}}) \sim (8, 133, 0.002 \text{ s})$. Note that the twist relaxation time is very long compared to bend and splay as well as the characteristic length scales of the director distortions are comparable; moreover, the timescale of $\sim 100 \text{ s}$ for twist relaxation is in rough agreement with the observed crossover time for particle motion perpendicular to $\mathbf{n}_0$.

To understand more deeply how the director field distortions can affect particle diffusion dynamics, we compute the variation of each pure distortion (splay, twist, and bend) due to a small particle displacement ($\Delta x_p, \Delta y_p \ll d$) either parallel or perpendicular to $\mathbf{n}_0$; here we utilize class 1 spheres because a model describing the distortions is available [27]. The calculated splay, twist, and bend distortions are plotted in Figs. 3(f)–3(h) for a stationary sphere. It is apparent that all modes of distortion are present. In Figs. 3(i)–3(n), we plot the magnitude of the change in these distortions due to small particle displacements ($\Delta x_p, \Delta y_p \sim 4.5 \text{ nm}$) perpendicular [Figs. 3(i)–3(k)] and parallel [Figs. 3(i)–3(n)] to $\mathbf{n}_0$. These are the director fluctuations that must relax back to equilibrium after the displacement. Notably, the plots [Figs. 3(i)–3(n)] suggest that the largest changes in $\mathbf{n}$ are associated with twist for particle motion perpendicular to $\mathbf{n}_0$; furthermore, significantly less overall change in $\mathbf{n}$ is observed for motion parallel to $\mathbf{n}_0$. These findings, and the relative timescales for relaxation estimated above, provide strong evidence that long-lived twist distortions play a dominant role in affecting diffusion dynamics in LCLCs.

In summary, the diffusion of spheres in LCLCs is quite different from diffusion in thermotropic LCs. The primary origin of these differences is the unusually small twist elastic constant of LCLCs. Because twist distortions are energetically cheap, the director configuration on each side of the particle is locally chiral, leading to twisted tails that extend much farther away from the particle than the splay and bend distortions of pure quadrupoles. We showed that these differences in twist uniquely affect particle dynamics, both diffusive and subdiffusive motions, as well as the timescales for these processes. Further, differences in diffusion constants and diffusion anisotropy are found for the two chiral director configurations. All of these phenomena are manifestations of the giant twist elastic anisotropy characteristic of LCLCs. Thus, twist effects can be expected to influence our ability to control micro- and nanoparticles in LCs.
